Abstract. In order to achieve greater coding efficiency compared with the previous video coding standards, various advanced coding techniques are used in the High Efficiency Video Coding (HEVC) standard, such as a flexible partition and a large number of intra prediction modes. However, these techniques lead to much greater complexity that restricts HEVC from real-time applications. To solve this problem, a fast intra mode decision algorithm is proposed in this paper that uses the block’s textural properties to determine the partition depth range and decide whether to split or skip smaller sizes of the coding unit. Besides that, the number of candidate modes for the rough mode decision process is also reduced depending on the block’s property. Experimental results for the recommended test sequences by the JCT-VC show that the proposed algorithm can save an average of 44% encoder time with a slight loss in performance compared to the reference software HM-16.20.

Keywords: HEVC/H.265, Video Compression, Mode Decision, Intra-frame Prediction, Coding Tree Unit.

1 Introduction

The rapid development of social networks and the exchange of multimedia content sets many new requirements for transmission and storage systems. In terms of video compression, although H.264/AVC (Advanced Video Coding) [1] does a pretty good job of delivering compressed video to users, it has reached its limit of modernization, and new standards need to be developed to replace it. The international video coding standard H.265/HEVC (High Efficiency Video Coding) developed in 2013 [2] can reduce bitrate by 50% while ensuring equivalent quality compared to its predecessor H.264 [3]. This effectiveness is obtained through adaptive coding techniques, such as flexible partition structures, advanced and adaptive predictions, improved deblocking filter, and entropy coding. On the other hand, this advantage comes with highly increased computational complexity, so the development of complexity reduction schemes for HEVC is one of the most crucial research topics in the field of video compression.

This paper focuses on improving the intra-frame coding - one important process in HEVC by early deciding to split the block and select the best suitable candidate modes. The rest of this paper is organized as follows. In Section 2, the intra-frame coding is briefly introduced. The proposed algorithm is presented in Section 3. Section 4 provides the experimental results, and Section 5 concludes this paper.

2 Intra prediction in HEVC

Instead of using macroblock as in H.264, HEVC uses the coding tree unit (CTU). Using the quad-tree partitioning technology, CTU can be split into coding units (CU) - the basic unit of separation, which has sizes from $64 \times 64$ to $8 \times 8$, corresponding to a depth of 0 to 3 (Fig. 1a). Based on the partition depth, CU can be recursively split into four equal CUs. The optimal CTU partition is determined using the rate-distortion cost (RDcost). In intra-frame coding, each CU is divided into prediction units (PU), which will select the optimal predictions from 35 modes, including Planar mode (mode 0 - for a slowly changing area), DC mode (mode 1 - more suitable for a homogeneous area) and 33 angular modes (mode 2 - 34 for different texture directions) (Fig. 1b). Thus, the efficiency of intra coding increases, but with a significant computational load, even though the official reference software HM [4] uses a fast three-step encoding algorithm [5–7] with a combination of rough mode decision (RMD) and rate-distortion optimization (RDO) processes (Fig. 2) since for each PU, the encoder must calculate the RDcost for all 35 modes, while the maximum number of PU in a CTU is 341.

Recently, much work has been published that offers various solutions to reduce the computational complexity of the intra mode decision process in HEVC. In general, they can be divided into two main types: optimization of the partitioning process of CU or PU [8–14] and adaptive selection of candidate modes for PU [9–11, 13, 19]. In these works, the coding information such as RDcost, Hadamard cost [9–12], or textural analysis [8] is used to decide the partition size on CU or PU. Decision trees [15], Bayesian

![Fig. 1. Example of splitting CTU into CUs and corresponding quad-tree (a) and intra modes (b) in HEVC](image-url)
decisions [16], or other machine learning techniques are also used to predict the unit sizes. The number of input modes for the prediction process can be reduced by utilizing the gradient histogram distribution [16], the correlation of the corresponding blocks in the adjacent frames [18], or statistical analysis of mode distribution [19]. Whatever technique is used, these approaches have shown their effectiveness when efficiently reduce the coding complexity.

Based on the analysis of existing works, this paper proposes a fast algorithm for intra-frame coding in HEVC, which allows making an early decision on CTU splitting and adaptively choosing candidates for the prediction process.

3 Proposed fast intra mode decision algorithm

3.1 CTU depth range determination

CU can have a size from $64 \times 64$ to $8 \times 8$, with the intra PU varying from $64 \times 64$ to $4 \times 4$. The flexible structure in HEVC shows its effectiveness since the encoder can use CU in different sizes for different areas in the frame. To analyze the correlation between the quad-tree partition and the textural features of a region, Fig. 3 shows an enlarged part of the frame of the "BasketballDrive" sequence encoded by the HM. It can be shown that in homogeneous areas or areas with a smooth texture, CUs are always selected in large sizes, while small CUs are suitable for more complex areas with rich details. The optimal CU is determined for each area by checking all possible sizes, in other words, all separation depths. This process can cause redundancy and increase computational complexity since in some homogeneous areas, there is no need to check the small sizes of the CU. If the optimal CU size or partition depth range can be decided at the early stage, the wasteful search process of intra mode will be skipped, and thus a considerable amount of complexity can be significantly reduced in HEVC.

Based on the relationship between CU size and texture complexity, an algorithm will be proposed for quickly determining the depth of the CTU, according to which the encoder can collapse the search area to reduce the computational burden of the partitioning process.

The texture complexity of an area or block is strongly related to its samples’ luminance value. The degree of variation in the luminance value in an $N \times N$ block is determined as follows:

$$L_{N \times N} = \frac{1}{N^2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} (Y(i,j) - Y_a(i,j))^2,$$  (1)
where \( Y(i,j) \) and \( Y_a(i,j) \) are the luminance values at \((i,j)\) and the average luminance value of the current block, respectively. \( L_{N\times N} \) represents the different luminance parameter of the current block. The more sharply the different luminance values change, the larger value of \( L_{N\times N} \) is obtained.

The value of \( L_{N\times N} \) changes very quickly when the luminance value in the block changes. According to \( L_{N\times N} \), we classify the block into homogeneous, middle texture, and complex texture. The encoder may terminate the split if the block is homogeneous. Otherwise, a split decision may be made early for blocks with the complex textural property.

\[
\begin{align*}
L \leq P_1 & \quad \text{homogeneous block;} \\
P_1 < L < P_2 & \quad \text{middle texture block;} \\
L \geq P_2 & \quad \text{complex texture block,}
\end{align*}
\]

(2)

where \( P_1, P_2 \) are lower and upper thresholds.

In our algorithm, to avoid calculating complexity for all block sizes, 16 × 16 CU is selected as the base block. A 32 × 32 CU is considered complex if at least one of the four 16 × 16 CUs inside it is complex. Similarly for 64 × 64 CU. In other cases, the texture of the 32 × 32 CU is determined by the value \( L_{16\times16}^{Max} \) following Eq. 3, while Eqs. 1 and 2 are used for 32 × 32 CU, and the textural property of the block of size 64 × 64 is obtained from \( L_{32\times32}^{Max} \).

\[
\begin{align*}
L_{N\times N}^{Max} \leq P_1 & \quad \text{homogeneous block;} \\
P_1 < L_{N\times N} < P_2 & \quad \text{middle texture block;} \\
L_{N\times N}^{Max} \geq P_2 & \quad \text{complex texture block,}
\end{align*}
\]

(3)

where \( L_{N\times N}^{Max} = \max\{L_{N\times N}^k\}, k = 0, \ldots, 3. \)
Since a split decision was made for the CU, the depth of the CTU can be determined in advance, so that the encoder can skip unnecessary depths. Let $D_{\text{min}}$ and $D_{\text{max}}$ denote the minimum and maximum depth of the current CTU:

$$D_{\text{min}} = \begin{cases} 
0 & \text{if} \ CU_{64 \times 64} \text{ homogeneous}; \\
1 & \text{if} \ \exists \ CU_{32 \times 32} \text{ middle texture}; \\
2 & \text{otherwise}.
\end{cases}$$  \quad (4)

$$D_{\text{max}} = \begin{cases} 
0 & \text{if} \ CU_{64 \times 64} \text{ homogeneous}; \\
1 & \text{if} \ 4 \ CU_{32 \times 32} \text{ homogeneous}; \\
2 & \text{if} \ 16 \ CU_{16 \times 16} \text{ homogeneous}; \\
3 & \text{if} \ \exists \ \text{complex texture block} \ CU_{16 \times 16}.
\end{cases}$$  \quad (5)

Thus, based on texture complexity, the early decision to split or terminate splitting is made at the CU level, while the optimal depth range is made for the CTU. As a result, the computational cost of determining the optimal block is reduced.

### 3.2 Adaptive candidate modes selection

Statistical analysis of common test sequences shows that the optimal modes’ distributions are not similar for all 35 intra modes. In most of the cases, modes 0 (Planar), 1 (DC), 10 (horizontal mode), and 26 (vertical mode) have larger proportions than other modes, where mode 0 has the highest proportion, and mode 1 has a second proportion, as many PU have relatively smooth textures after CU partition and most of them choose mode 0 or 1 as the optimum mode. Since the textural feature of most sequences has clear vertical or horizontal directions, the proportions of modes 10 and 26 are higher than other angle modes. Furthermore, the adjacent modes to those modes are relatively higher, while the proportions of the rest are insignificant. Hence, the number of input modes for intra prediction can be reduced, focusing on high probability modes to cutoff the complexity of the prediction process.

The original intra mode selection in HM will be modified as follows: instead of all 35, at the first stage of the prediction process, only most probability modes and angular modes in equal distances (List1) are tested using the RMD process to find modes with the lowest cost. After that, one more rough mode decision step (RMD2) was added to check a maximum of 4 more modes surrounding the best results of the first RMD. As a result, the minimum and the maximum number of modes that need to calculate the Hadamard costs are 11 and 15.

$$List1 = \{0, 1, 2, 6, 10, 14, 18, 22, 26, 30, 34\}. \quad (6)$$

The block’s texture properties can also be used to further reduce the total number of candidate modes for intra prediction. Let classify PUs into three categories depending on their sizes: low complex (homogeneous) (PU $64 \times 64$), middle complex (PU $32 \times 32$, PU $16 \times 16$), and complex (PU $8 \times 8$, PU $4 \times 4$). Table 1 shows the distribution of optimal modes for PU in low and middle complex groups. It can be seen that for homogeneous
Table 1. Distributions of optimum modes in different PUs

<table>

</tr>
</tbody>
</table>

or middle complex PU, the number of candidate modes can be reduced to save the computational load.

Candidate modes for different PUs are given in Table 2, where for blocks of high complexity (PU $8 \times 8$ and PU $4 \times 4$) we will leave as in Eq. 6.

Table 2. Candidate modes for various block types

<table>
<thead>
<tr>
<th>Block type</th>
<th>Candidates</th>

<td>0, 1, 6, 10, 14, 22, 26, 30</td>
</tr>
<tr>
<td>Complex texture</td>
<td>0, 1, 2, 6, 10, 14, 18, 22, 26, 30, 34</td>
</tr>
</tbody>
</table>

The overall algorithm, including early determination of the CTU depth range, early decision of the CU splitting and adaptive selection of candidate modes, is as follows:

**Step 1.** Classify CUs into a homogeneous, middle, and complex texture.

**Step 2.** Predict the depth range $[D_{\text{min}}, D_{\text{max}}]$ based on the texture properties of the CUs.

**Step 3.** Select a candidate list for PU in different areas. Calculate RMD.

**Step 4.** Calculate RMD2 for additional modes. Add most probable modes (MPM).

**Step 5.** Calculate the RDO. Choose the best mode.

4 Experimental results

The proposed algorithm was implemented in HM-16.20, and several standard test sequences of different categories were selected for testing. All frames were encoded with the All Intra-Main configuration and four values of the quantization parameter (QP): 22, 27, 32, 37 [20]. All experiments are carried on macOS Mojave version 10.14.x with Intel® Core™ i5-5257U @ 2.7GHz and 8GB of RAM.

The proposed algorithm’s effectiveness is estimated using two metrics: Bjontegaard delta bitrate (BD-BR) and Bjontegaard delta peak-signal-to-noise (BD-PSNR) [21]. Encoding time-saving ($\Delta T'$) is used to evaluate computational complexity.

The comparative results of the proposed algorithm and the original HM-16.20 are shown in Table 3. The proposal can reach up to 63% of time-saving, while BD-BR increased on average by 2.54%, and the loss of BD-PSNR was 0.074dB.

5 Conclusion

In order to reduce the computational complexity of the intra mode decision process in HEVC, this paper proposes a fast algorithm that uses the correlation between the textural property of an area and the CTU partitioning process. The variation degree of the luminance value is used to evaluate a block, from which the encoder can make a decision on CU splitting and determine the CTU depth range. Also, based on the PU sizes, the number of candidate modes for the selection process is significantly reduced. Experimental data show that the proposed algorithm can save about 44% of the encoding time while maintaining almost the same performance.
