OPC-UA based IIoT and CPS interoperability validation

Jaekel, Frank-Walter

^a Fraunhofer Institute Production Systems and Design Technology, Pascalstr. 8-9, Berlin, D-10587, Germany

Abstract

The rise of Cyber Physical Systems (CPS), Industry 4.0 and Industrial Internet of Things (IIoT) leads to the connection of production facilities via intranet as well as to the Internet. Machines are now IoT objects. This enables new processes in terms of digitalization, but also challenges in terms of security, performance, robustness and interoperability. The related changes in technologies and communication opportunities is also effecting the enterprise organization. The paper describes test cases, application scenarios and tools for ensuring compliance between enterprise IT infrastructure and industrial internet of things components using OPC-UA.

Keywords 1

IoT, IIoT, CPS, interoperability, OPC-UA

1. Introduction

In the past, the production facilities were rarely digital connected to each other within the production lines and to the enterprise applications. Software applications were locally adapted to the machines and executed. The insertion and set-up of the equipment referred to physical and logistical parameters of the machines to allow a seamless exchange of equipment within the production process. The digital plug-and-product of the digital components of the production equipment was underestimated in terms of conformity and interoperability.

The rise of Cyber Physical Systems (CPS), Industry 4.0 and Industrial Internet of Things (IIoT) leads to a dramatic change. Production facilities are now able to connect to each other, but also to the intranet as well as to the Internet. Machines are now IoT objects able to be interconnected with enterprise applications internally as well as across the supply chain network. This enables new processes in terms of digitalization, but also challenges in terms of security, performance, robustness and interoperability. The related changes in technologies and communication opportunities is also effecting the enterprise organization. The responsibilities on the shop floor requires now production and IT competencies because hardware and software components of the machinery are integral part.

The ramp-up of machines requires tests of conformity with the company's IT infrastructure to ensure a smooth plug-and-play. In the past after the ramp-up we had usually the notion of "do not change a running" system. This changed with connections to enterprise applications requiring continues updates and also updates of interfaces. Therefore, test mechanisms are important to check and control the setup and changes of interfaces. The paper focus on related test cases and application scenarios using OPC-UA [1].

The description of specific use cases and test cases supports the identification of the need for validation of communication interfaces. Specific problems from practice are described and possible approaches to solutions are suggested.

The test cases and application scenarios presented in this presentation for securing the interoperability of systems have been developed on the basis of information from standardization, OPC-UA user conferences, discussions with system suppliers and developments in the German national "Internet of Things Test" (IoT-T) [5].

2. Test cases to compare OPC-UA information models

A number of test cases have been identified that are critical to the interaction between digital plant interfaces and enterprise applications. The presence of the required information elements is of importance, which are represented in the OPC-UA information model by nodes with a specific structure. [3]

2.1. Information model

An important prerequisite for the test is the standardized structure of information models in OPC-UA. This allows specific properties to be tested according to fixed rules. The information model is based on a series of nodes with an internal characteristics structure. The nodes can be networked with other nodes and stand in different relations. Specific nodes, for example for standard types, are specified by the OPC Foundation [4] for the information models.

In OPC-UA nodes can be identified by IDs, names and their position within an information structure. The IDs must always be present and unique within an information model. A node can represent specific values and interrelations such as a temperature value. It can be uniquely identified by its ID. In this case it must be checked whether an OPC UA application has implemented all required nodes with their corresponding IDs, such as for a temperature sensor the correct temperature node.

In addition to the IDs, the nodes can also be distinguished from each other by their names. However, since the names of the nodes do not have to be unique according to the OPC UA specification, this individual check is not sufficient. In addition to the unique identification of nodes, the IDs are also used for referencing one another. A node therefore has a number of references to other nodes. Structures such as component and type relationships and corresponding paths can be derived from these references. Recursive paths can also be created, which must be recognized and taken into account during the check.

The comparison of OPC-UA information models is shown schematically in figure 1. An information model can map a subset of the nodes of another information model. Thus, it is possible that an installation provides more nodes than expected.

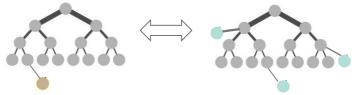

Figure 1: Comparison of OPC-UA information models

2.2. Investigated test cases

An important prerequisite for the test is the standardized structure of the information models in OPC-UA. This allows certain properties to be tested according to fixed rules. The information model is based on a series of nodes with an internal characteristics structure. The nodes can be networked with other nodes and have different relationships to each other. Specific nodes, for example for standard types, are specified by the OPC Foundation [4] for the information models. Based on the OPC UA information model, the IoT-T project has created a number of test cases which play a decisive role in the interaction between digital plant interfaces and enterprise applications. The existence of the required information elements must be recognized and ensured. These are represented in the OPC UA information model by a node structure. The following cases are currently being defined and implemented in the test environment:

- NodeId does not exist (missing node)
- BrowseName does not exist (missing node)
- Reference is not available
- Path within the node structure is not equal

- Additional nodes were identified
- ParentNodeID does not match
- Attributes do not match
- Shifting the namespace index of NodeIDs
- Recursive definitions

The test cases are related to a source and a target information model e.g. the target information model can reflect a specification which has to be covered by the source information model. Three of the test cases are describe exemplarily in the next chapters.

2.2.1. NodeID does not exist

The target information model specifies a number of nodes with corresponding IDs. If a node with the specified ID cannot be found in the source information model provided by an OPC-UA server, this node does not exist in the application. However, an error may have occurred while implementing the node in the application. Part of the ID is an identifier, which can be a number or a word. The distinction between word and number is crucial to find this node in the application. The following cases were identified:

- NodeID does not exist in the specification, but the BrowseName does. This results in a warning because the BrowseName is not requested to be unique.
- NodeID and the BrowseName does not exist in the specification. An error appears because the node cannot be found.
- NodeID exits but the BrowseName different. A warning appears because of potential conflicts in the date model and between data models.

2.2.2. Path within the structure not equal

OPC-UA NodeIDs are used for references, which then result in a structure of nodes. Within this structure the references are equivalent to paths and each node is uniquely identifiable by a path. An unequal path between source and target information model thus indicates an incorrect implementation. The following cases were identified:

- Paths are indirectly indicated by the parent-child relation.
- Is checked indirectly by comparing the ParentNodeID and references from the specification.

2.2.3. Additional nodes identified

The check between information models provides feedbacks according information in one information model which is not reflected in the other information model. We can have tree reasons

- The additional information are missing and needs to be implemented.
- Further information are available for other applications.
- An error in the name or ID which results in a mismatch and duplicate of an information with different identification.

3. Test environment

Within the framework of the IoT-T project [5], Fraunhofer IPK developed the following software components based on the requirements from industry [6, 7]:

- CPS Validation Adapter (CPSVA) available as Open Source,
- Deviation Analyser (DA) available as Open Source,
- CPS Emulator (CPSE).

The three components build a test environment concerning interoperability of OPC-UA information models. The CPSVA can be used as an easy-to-use software application. A user does not require

detailed knowledge of OPC-UA. The CPSVA uses a generic pre-defined test process and therefore does not require a special test description. Testing is configured by an OPC-UA information model provided by the user. Currently the following features are provided:

- No programming of tests only reading the information model to check an OPC UA server,
- Few OPC UA knowledge required at the user's end to perform tests,
- Quick verification of adjustments or changes in the information model,
- Exchange of OPC-UA Software Development Kits (SDKs) to avoid being bound to an SDK that may not fully implement the current OPC-UA framework.

DA has been developed to display and analyses the results of the CPSVA tests. This tool offers a simple user interface. The main features of the tool written in Java are

- Simple evaluation of the results,
- Easy finding of errors in the information model regarding the specification,
- User-friendly display of deviations,
- Clarity for finding and evaluating deviations,
- Easy expandability and adaptation of error tags when the CPSVA is expanded.

In order to test CPSVA and DA and to be able to run through use cases in the IoT-T project, a special OPC-UA server was also developed as a CPS emulator. The CPSE can perform some 'server side checks directly, as it checks whether a given information model can be read and implemented in the server.

The required information model corresponds to a specification by the user of a plant, which must be fulfilled by the digital interface of the enterprise IT infrastructure. File paths and IP addresses are defined in the test configuration. The results of the test are then a log file with detailed error descriptions and the information model found in the respective OPC-UA server. It does not matter whether the information model is hard-coded in the server or is read in by a configuration. With this, characteristics of OPC-UA servers of a physical machine, a digital twin, an emulation or even a cloud service can be checked.

The interaction between CPSVA and CPSE is reflected in the test algorithm, which is shown in the next chapter.

4. Application scenario

In the application scenarios, the needs and possible applications of CPS Validation are illustrated, especially with regard to the needs of industry. The test cases from chapter 3 are used to carry out appropriate checks for interoperability. The test cases are stored in the CPS Validation Adapter and the CPS Emulator.

In the IoT-T project, a number of scenarios were identified together with representatives from industry and standardization and tested exemplarily in demonstrators with the CPSVA:

- Digital plug and produce
- Checking standards with regard to information models (Companion Specs)
- Dynamic information models in manufacturing
- Integration of business applications (e.g. BDE, ERP, MES)
- Updating the digital interfaces of installations and company applications
- Integration of sensors and monitoring of key figures
- Cloud based production control and monitoring
- Forwarding the error message of a robot.

The application scenario "dynamic information models in production" exemplifies the usage of the interface validation, below.

The flexibility of the manufacturing processes and the shorter reaction times to customer demands require a fast and as autonomous as possible adaptation of the provided manufacturing functions or services. This also influences the information provided via the interfaces between plants, company applications and users. Supplement a service means the extension of the OPC-UA information model at runtime. In this case the information model can grow over time and be reduced again. This also means that the validation must be made more flexible and, if necessary, must be used in a simulation in advance.

The test set-up with physical machine interfaces led to a number of adjustments and improvements in the CPSVA and CPSE. For this application, a demonstrator was set up which comprises the following steps:

- Start of production, with incomplete machine adapter, because the call of "Reset" is missing.
- Production stops, robot stops without putting back the gear wheel.
- Check with the CPS-VA where the deviation analysis is automatically carried out and displays the error.
- Errors in the information model are identified and errors in the information model are clarified.
- Error is corrected.
- Check of the corrected information model with the CPSVA. No more errors are detected.
- Complete process is started. Robot puts back gear after production..

This process was also built up semi-automatically from a corresponding enterprise model with the help of the concept for IPK's Modular Shopfoor IT [2].

5. Conclusion

OPC-UA information models are available as open source for testing, for example on GitHub. Sources are, among others, standardisation activities of the VDMA. In the project, these information models were used for tests, whereby the following experiences were gathered.

The analysis and testing of the standardised information models required several changes before the information models could be read in completely and without errors by the used OPC-UA server (CPS emulator). Changes included the insertion of NamespaceUris and the appending of nodes if they did not have a parent node.

After the standardised information models were readable. These could be tested against by the CPSVA. Depending on which information model was read in the CPSVA, it was tested against the information model already read in on the server.

The paper illustrates validation procedures and scenarios for IIoT OPC-UA interfaces to improve the on demand connectivity within enterprise infrastructures. The next step is to provide a distribution package for open source usage and to arrange further developments.
